

AWS Architecture

The following diagram describes the [Application] architecture:

Figure 1. [Application] Architecture

The following table lists the architectural elements in alphabetical order, providing additional context of the relationship between them:

Element	Description
Auxiliar Database	Replaces the Main Database during downtime, ensuring redundancy and data availability.
DNS Service	Returns the Load Balancer 's IP address to the End User when the End User requests it.
End User	Consumes the application's services.
Load Balancer	Routes requests from the End User to the Web Server and returns responses back to the End User .
Main Database	Stores Web Server data.
Route Table	Directs traffic to ensure the Load Balancer distributes requests evenly across Web

	Servers.
Web Server	Handles incoming requests, queries the Main Database , and responds to the End User .

Dataflow

The following steps describe a sequential explanation of the data flow in the web application architecture:

1. The **End User** queries the **DNS Service** to request the IP address of the **Load Balancer**.
2. The **DNS Service** returns the **Load Balancer**'s IP address to the **End User**.
3. The **End User** sends a request to the **Load Balancer**.
4. The **Load Balancer** redirects the request to a **Web Server** according to the settings in the **Route Table**.
5. The **Web Server** processes the request and queries data from the **Main Database** when needed.
6. The **Main Database** returns the queried data to the **Web Server**.
7. The **Web Server** processes the data from the **Main Database** and prepares a response for the **End User**.
8. The **Load Balancer** returns the **Web Server** response to the **End User**.
